ABSTRACT
Twitter is a new web application playing dual roles of online social networking and micro-blogging. Users communicate with each other by publishing text-based posts. The popularity and open structure of Twitter have attracted a large number of automated programs, known as bots, which appear to be a double-edged sword to Twitter. Legitimate bots generate a large amount of benign tweets delivering news and updating feeds, while malicious bots spread spam or malicious contents. More interestingly, in the middle between human and bot, there has emerged cyborg referred to either bot-assisted human or human-assisted bot. To assist human users in identifying who they are interacting with, this paper focuses on the classification of human, bot and cyborg accounts on Twitter. We first conduct a set of large-scale measurements with a collection of over 500,000 accounts. We observe the difference among human, bot and cyborg in terms of tweeting behavior, tweet content, and account properties. Based on the measurement results, we propose a classification system that includes the following four parts: (1) an entropy-based component, (2) a machine-learning-based component, (3) an account properties component, and (4) a decision maker. It uses the combination of features extracted from an unknown user to determine the likelihood of being a human, bot or cyborg. Our experimental evaluation demonstrates the efficacy of the classification system.

1. INTRODUCTION
Twitter is a popular online social networking and micro-blogging tool, which was released in 2006. Remarkable simplicity is its distinctive feature. Its community interacts via publishing text-based posts, known as tweets. The tweet size is limited to 140 characters. Hashtag, namely words or phrases prefixed with a # symbol, can group tweets by topic. For example, #Haiti and #Super Bowl are the two trending hashtags on Twitter in January 2010. Symbol @ followed by a username in a tweet enables the direct delivery of the tweet to that user. Unlike most online social networking sites (i.e., Facebook and MySpace), Twitter’s user relationship is directed and consists of two ends, friend and follower. In the case where the user A adds B as a friend, A is a follower of B while B is a friend of A. In Twitter terms, A follows B. B can also add A as his friend (namely, following back or returning the follow), but is not required. From the standpoint of information flow, tweets flow from the source (author) to subscribers (followers). More specifically, when a user posts tweets, these tweets are displayed on both the author’s homepage and those of his followers.

Since 2009, Twitter has gained increased popularit. As reported in June 2010, Twitter is attracting 190 million visitors per month and generating 65 million Tweets per day [30]. It ranks the 12th on the top 500 site list according to Alexa [5]. In November 2009, Twitter emphasized its value as a news and information network by changing the question above the tweet input dialog box from “What are you doing” to “What’s happening”. To some extent, Twitter is in the transition from a personal micro-blogging site to an information publish venue. Many traditional industries have used Twitter as a new media channel. We have witnessed successful Twitter applications in business promotion [1], customer service [3], political campaigning [2], and emergency communication [21, 35].

The growing user population and open nature of Twitter have made itself an ideal target of exploitation from automated programs, known as bots. Like existing bots in other web applications (i.e., Internet chat [14], blogs [34] and online games [13]), bots have been common on Twitter. Twitter does not inspect strictly on automation. It only requires the recognition of a CAPTCHA image during registration. After gaining the login information, a bot can perform most human tasks by calling Twitter APIs. More interestingly, in the middle between humans and bots have emerged cyborgs, which refer to either bot-assisted humans or human-assisted bots. Cyborgs have become common on Twitter. After a human registers an account, he may set automated programs (i.e., RSS feed/bot widgets) to post tweets during his absence. From time to time, he participates to tweet and interact with friends. Cyborgs interweave characteristics of both humans and bots.

Automation is a double-edged sword to Twitter. On one hand, legitimate bots generate a large volume of benign tweets, like news and blog updates. This complies with the Twitter’s goal of becoming a news and information network. On the other hand, malicious bots have been greatly exploited by spammers to spread spam or malicious contents. These bots randomly add users as their friends, expecting a few users to follow back1. In this way, spam tweets posted by bots display on users’ homepages. Enticed by the appealing text content, some users may click on links and get redirected to spam or malicious sites2. If human users are surrounded by ma-

---

1Some advanced bots target potential users by keyword search.
2Due to the tweet size limit, it is very common to use link shortening service on Twitter, which converts an original link to a short one (i.e., http://bit.ly/drUmsQ). The link illegibility favors bots to...
licious bots and spam tweets, their tweeting experience deteriorates, and eventually the whole Twitter community will be hurt. The objective of this paper is to characterize the different features of Twitter accounts, and to classify them into three categories, human, bot, and cyborg, accordingly. This will help Twitter manage the community better and help human users recognize who they are tweeting with.

In our study, we first conduct a series of measurements to characterize the differences among human, bot, and cyborg in terms of tweeting behavior, tweet content, and account properties. By crawling Twitter, we collect over 500,000 users and more than 40 million tweets posted by them. Then we perform a detailed data analysis, and find a set of useful features to classify users into the three classes. Based on the measurement results, we propose an automated classification system that consists of four major components: (1) the entropy component uses tweeting interval as a measure of user activity, and other intervals, which are not employed in previous research; (2) the account-level component uses tweet content to check whether text patterns contain spam or not; (3) the account properties component employs useful account properties, such as tweeting device makeup, URL ratio, to detect deviations from normal; (4) the decision maker is based on Linear Discriminant Analysis (LDA), and it uses the linear combination of the features generated by the above three components to categorized an unknown user as human, bot, or cyborg. We validate the efficacy of the classification system through our test dataset. We further apply the system to classify the entire dataset of over 500,000 users collected, and speculate the current composition of Twitter user population based on our classification results.

The remainder of this paper is organized as follows. Section 2 covers related work on Twitter and online social networks. Section 3 details our measurements on Twitter. Section 4 describes our automatic classification system on Twitter. Section 5 presents our experimental results on classification of humans, bots, and cyborgs on Twitter. Finally, Section 6 concludes the paper.

2. RELATED WORK

Twitter has been widely used since 2006, and there are some related literature in twittering [24, 25, 42]. To better understand micro-blogging usage and characteristics, Ja et al. [24] studied over 70,000 Twitter users and categorized their posts into four main groups—daily chatter (e.g., “going out for dinner”), conversations, sharing information or URLs, and reporting news—and further classified their roles by link structure into three main groups—information source, friends, and information seeker. Their work also studied (1) the growth of Twitter, showing a linear growth rate; (2) its network properties, showing the evidence that the network is scale-free like other social networks [27]; and (3) the geographical distribution of Twitter users, showing that major Twitter users are located in the US, Europe, and Japan. Kenneth et al. [25] and Kawasaki et al. [26] analyzed humans and bots in Yahoo! chat and developed a classification system to detect bots using entropy-based and machine-learning-based classifiers, both of which are used in our classification system as well. In addition, as Twitter is text-based, email spam filtering techniques are also relevant [17, 40, 43]. However, Twitter posts are much shorter than emails and spaced out over longer periods of time than for instant messages, e.g., hours rather than minutes or seconds.

Twitter also differs from most other network services in that automation, e.g., message feeds, is a major feature of legitimate Twitter usage, blurring the lines between bot and human. Twitter users can be grouped into four categories: humans, bots, bot-assisted humans, and human-assisted bots. The latter two, bot-assisted humans and human-assisted bots, can be described as cyborgs, a mix between bots and humans [41].

3. MEASUREMENT

In this section, we first describe the data collection of over 500,000 Twitter users. Then, we detail our observation of user behaviors and account properties, which are pivotal to automatic classification.

3.1 Data Collection

Here we present the methodology used to crawl the Twitter network and collect detailed user information. Twitter has released a set of API functions [39] that support this purpose. Thanks to Twitter’s courtesy of including our test account to its white list, we can make API calls up to 20,000 per hour. This eases our data collection. To diversify our data sampling, we employ two methods to collect the dataset covering more than 500,000 users. The first method is Depth-First Search (DFS) based crawling. The reason we choose DFS is that it is a fast and uniformed algorithm for traversing a network. Besides, DFS traversal implicitly includes the information about network locality and clustering. Inspired by [15, 18], we randomly select five users as seeds. For
To develop an automatic classification system, we need a training data set that contains known samples of human, bot, and cyborg. Among collected data, we randomly choose different samples and classify them by manually checking their user logs and homepages. The training set includes one thousand users per class of human, bot and cyborg, and thus in total there are three thousand classified samples. A test set of three thousand samples is created in a similar way. Both sets serve as the ground truth dataset, containing fied samples. A test set of three thousand samples is created in a bot and cyborg, and thus in total there are three thousand classification. Most information is returned in the format of XML or JSON. We totally collect 512,407 users on Twitter combining both methods.

3.2 Ground Truth Creation

To develop an automatic classification system, we need a training data set that contains known samples of human, bot, and cyborg. Among collected data, we randomly choose different samples and classify them by manually checking their user logs and homepages. The training set includes one thousand users per class of human, bot and cyborg, and thus in total there are three thousand classified samples. A test set of three thousand samples is created in a similar way. Both sets serve as the ground truth dataset, containing known samples of human, bot, and cyborg. Since the Twitter timeline updates the crawler can repeatedly call the timeline API. During the same time window of the DFS crawl, this method contributes 82,984 users to the dataset. We totally collect 512,407 users on Twitter combining both methods.

3.3 Data Analysis

As mentioned before, Twitter API functions support detailed user information query, ranging from profile, follower and friend lists to posted tweets. In the above crawl, for each user visited, we call API functions to collect abundant information related with user classification. Most information is returned in the format of XML or JSON. We develop some toolkits to extract useful information from the above well-organized data structures. Our measurement results are presented in the question-answer format.

Q1. Does automation generate more tweets?

To answer Question 1, we measure the number of tweets posted in a user’s lifetime. Figure 1 shows the cumulative distribution function (CDF) of the tweet counts, corresponding to the human, bot and cyborg categories. It is clear that cyborg posts more tweets than human. However, large proportion of cyborg accounts are registered by commercial companies and websites as a new type of media channel and customer service. Most tweets are posted by automated tools (i.e., RSS feed widgets, Web 2.0 integrators), and the volume of such tweets is considerable. Meanwhile, a bot is generated by some employees who communicate with customers from time to time. Thus, the high tweet count in the cyborg category is attributed to the combination of both automatic and human behaviors in a cyborg. It is surprising that bot generates fewer tweets than human. We check the bot accounts, and find out the following fact. In its active period, bots tweets more frequently than human. However, bots tend to take long-term hibernation. Some are either suspended by Twitter due to extreme or aggressive activities, while the others are deactivation and can be activated to be used. Some are automatic updates of blog entries or RSS feeds. The third is like automatic updates of blog entries or RSS feeds, and the last is the aggressive following behavior. In order to gain attention from human users, bots do mass following and un-following within a short period of time. Cyborgs are either human-assisted bots or bot-assisted humans. The criterion for classifying a cyborg is the evidence of both human and bot participation. For example, a typical cyborg account may contain different types of tweets. A large proportion of tweets carry characteristics of human-like intelligence and auto-tweeted-like contents, while the others are automatic updates of RSS feeds. It represents a usage model, in which the human uses his account from time to time while the cyborg widget constantly runs on his desktop and posts RSS feeds of his favorite news channel. Lastly, the uncertain category is for non-English users and those without enough tweets to classify. The samples that are difficult and uncertain to classify fall into this category, and are discarded. Some Twitter accounts are set as “private” for privacy protection, and their web pages are only visible to their friends. We do not include such type of users in the classification either, because of their inaccessibility.

Q2. Do bots have more friends than followers?

A user’s tweets can only be delivered to those who follow him. A common strategy used by bots is following a large number of users (either targeted with purpose or randomly chosen), and expecting some of them will follow back. Figure 2 shows the scatter plots of the numbers of followers and friends for the three categories. For better illustration, the scale is chopped and a small amount of extraordinary points are not included. In Figure 2, there are three different groups of users: group 1 where the number of one’s followers is clearly

act with friends. For example, he may write a post like “I just saw Yankees lost again today. I think they have to replace the starting pitcher for tomorrow’s game.” The content carries intelligence and originality. Specificity means that the tweet content is expressed in relatively unambiguous words with the presence of consciousness [36]. For instance, in reply to a tweet like “How you like iPad”, a specific response made by human may be “I like its large touch screen and embedded 3G network”. On the other hand, a generic reply could be “I like it”. The criteria for identifying a bot are listed as follows. The first is the lack of intelligent or original content. For example, completely retweeting tweets of others or posting advertisements indicates a lack of originality. The second is the excessive automation of tweeting, like automatic updates of blog entries or RSS feeds. The third is the abundant presence of spam or malicious URLs (i.e., phishing or malware) in tweets or the user profile. The fourth is repeatedly posting duplicate tweets. For example, the topic of the redirected web page does not match the tweet description. The last is the aggressive following behavior. In order to gain attention from human users, bots do mass following and un-following within a short period of time. Cyborgs are either human-assisted bots or bot-assisted humans. The criterion for classifying a cyborg is the evidence of both human and bot participation. For example, a typical cyborg account may contain different types of tweets. A large proportion of tweets carry characteristics of human-like intelligence and auto-tweeted-like contents, while the others are automatic updates of RSS feeds. It represents a usage model, in which the human uses his account from time to time while the cyborg widget constantly runs on his desktop and posts RSS feeds of his favorite news channel. Lastly, the uncertain category is for non-English users and those without enough tweets to classify. The samples that are difficult and uncertain to classify fall into this category, and are discarded. Some Twitter accounts are set as “private” for privacy protection, and their web pages are only visible to their friends. We do not include such type of users in the classification either, because of their inaccessibility.

Q1. Does automation generate more tweets?

To answer Question 1, we measure the number of tweets posted in a user’s lifetime. Figure 1 shows the cumulative distribution function (CDF) of the tweet counts, corresponding to the human, bot and cyborg categories. It is clear that cyborg posts more tweets than human. However, large proportion of cyborg accounts are registered by commercial companies and websites as a new type of media channel and customer service. Most tweets are posted by automated tools (i.e., RSS feed widgets, Web 2.0 integrators), and the volume of such tweets is considerable. Meanwhile, a bot is generated by some employees who communicate with customers from time to time. Thus, the high tweet count in the cyborg category is attributed to the combination of both automatic and human behaviors in a cyborg. It is surprising that bot generates fewer tweets than human. We check the bot accounts, and find out the following fact. In its active period, bots tweets more frequently than human. However, bots tend to take long-term hibernation. Some are either suspended by Twitter due to extreme or aggressive activities, while the others are deactivation and can be activated to be used. Some are automatic updates of blog entries or RSS feeds. The third is like automatic updates of blog entries or RSS feeds, and the last is the aggressive following behavior. In order to gain attention from human users, bots do mass following and un-following within a short period of time. Cyborgs are either human-assisted bots or bot-assisted humans. The criterion for classifying a cyborg is the evidence of both human and bot participation. For example, a typical cyborg account may contain different types of tweets. A large proportion of tweets carry characteristics of human-like intelligence and auto-tweeted-like contents, while the others are automatic updates of RSS feeds. It represents a usage model, in which the human uses his account from time to time while the cyborg widget constantly runs on his desktop and posts RSS feeds of his favorite news channel. Lastly, the uncertain category is for non-English users and those without enough tweets to classify. The samples that are difficult and uncertain to classify fall into this category, and are discarded. Some Twitter accounts are set as “private” for privacy protection, and their web pages are only visible to their friends. We do not include such type of users in the classification either, because of their inaccessibility.

Q2. Do bots have more friends than followers?

A user’s tweets can only be delivered to those who follow him. A common strategy used by bots is following a large number of users (either targeted with purpose or randomly chosen), and expecting some of them will follow back. Figure 2 shows the scatter plots of the numbers of followers and friends for the three categories. For better illustration, the scale is chopped and a small amount of extraordinary points are not included. In Figure 2, there are three different groups of users: group 1 where the number of one’s followers is clearly

4,431,923 tweets in the training set, and 3,918,172 tweets in the test set.
due to their message feeds and high levels of news and blog activity on Saturday and Sunday. The cyborg activity trends are mainly Monday to Friday, and less active during the weekend, Saturday and Sunday, bots have roughly the same activity level every day.

While humans are most active during the regular workdays, from Monday to Friday, and less active during the weekend, Saturday and Sunday. The cyborg activity trends are mainly Monday to Friday, and less active during the weekend, Saturday and Sunday.

Twitter users show clear differences among the three categories. Figure 4(b) presents the tweeting percentage of the three user categories.

4(b) present the tweeting percentage of the three user categories. The cyborg activity trends are mainly Monday to Friday, and less active during the weekend, Saturday and Sunday. The cyborg activity trends are mainly Monday to Friday, and less active during the weekend, Saturday and Sunday.

Figure 4(a) and Figure 4(b) present the tweeting percentage of the three user categories. The cyborg activity trends are mainly Monday to Friday, and less active during the weekend, Saturday and Sunday. The cyborg activity trends are mainly Monday to Friday, and less active during the weekend, Saturday and Sunday.

In the human category, as shown in Figure 2(a), the majority of the nodes belong to group III, implying that the number of their followers is close to that of their friends. This result complies with [27], revealing that human relationships are typically reciprocal in social networks. Meanwhile, there are quite a few nodes belonging to group I with far more followers than friends. They are usually accounts of celebrities and famous organizations. They generate interesting media contents and attract numerous subscribers. For example, the singer Justin Timberlake has 1,645,675 followers and 39 friends (the ratio is 42,197-to-1). In the bot category, many nodes belong to group II, as shown in Figure 2(b). Bots add many users as friends, but few follow them back. Unsolicited tweets make bots unpopular among the human world. However, for some bots, the number of their followers is close to that of their friends. This is due to the following reasons. First, Twitter imposes a limit on the ratio of followers over friends to suppress bots. Thus, some advanced bots un-follow their friends if they do not follow back within a certain amount of time. Those bots cunningly keep the ratio close to 1. Figure 3 shows the ratio of followers over friends for the three categories. The human ratio is the highest, and the bot ratio is the lowest.

Q3. Are there other temporal properties of Twitter users useful for differentiation among human, bot, and cyborg? Many research works like [11] and [9] have shown the weekly and diurnal access patterns of humans in the Internet. Figure 4(a) and Figure 4(b) present the tweeting percentage of the three user categories on a daily and hourly basis, respectively. The weekly behavior of Twitter users shows clear differences among the three categories. While humans are most active during the regular workdays, from Monday to Friday, and less active during the weekend, Saturday and Sunday, bots have roughly the same activity level every day of the week. Interestingly, cyborgs are the most active on Monday and then slowly decrease during the week and become the least active on Saturday and Sunday. The cyborg activity trends are mainly due to their message feeds and high levels of news and blog activity at the start of a week. Similarly, the hourly behavior of human is more active during the daytime that mostly overlaps with office hours. The bot activity is nearly even except a little drop in the deep of night. Some advanced bots have the setting of "only tweet from a time point to another," which helps save API calls [37]. Thus, they can tweet more in the daytime to better draw the attention of humans.

Figure 5 shows account registration dates grouped by quarter due to space limit. We draw two conclusions from the figure. First, the majority of accounts (80.0% of humans, 94.8% of bots, and 71.1% of cyborgs) were registered in 2009. It confirms the skyrocketing development of Twitter in 2009. Second, we do not find any bot or cyborg in our ground truth dataset earlier than March, 2007. However, human registration has continued increasing since Twitter was founded in 2006. Thus, old accounts are less likely to be bots.

Q4. How do users post tweets? Manually or via auto piloted tools? Twitter supports a variety of channels to post tweets. The device name appears below the tweet it posts prefixed by "from." Our whole dataset includes 41,991,545 tweets posted by 3,648 distinct devices. The devices can be roughly divided into the following four categories. (1) Web, the user logs into Twitter and posts tweets via the website. (2) Mobile devices, there are some programs exclusively running on mobile devices to post tweets, like Txt for text messages, Mobile web for web browsers on handheld devices, TwitterBerry for BlackBerry, and twidroid for Android mobile OS. (3) Registered third-party applications, many third-parties have developed their own applications using Twitter APIs to tweet, and registered them with Twitter. From the application standpoint, we can further categorize this group into sub groups including website integrators (twipic, bit.ly, Facebook), browser extensions (Tweetbar and Twitterfox for Firefox), desktop clients (TweetDeck and Seesmic Desktop), and RSS feeds/blog widgets (twitterfeed and Twitter for Wordpress). (4) APIs, for those third-party applications not registered or certificated by Twitter, they appear as "API" in Twitter.

Figure 6 shows the makeup of the above tweeting device categories. Twitter website is the most widely used that generates nearly half the tweets (46.78%), followed by third-party devices (40.18%). Mobile devices and unregistered API tools contribute 6.81% and 6.23%, respectively. Table 1 lists the top ten devices used by the human, bot, and cyborg categories, and the whole dataset. The whole dataset contains around 500,000 users, and the human, bot and cyborg categories equally contain 1,000 users in the training dataset.
RSS2Twitter, and Proxifeed are RSS feed widgets that automatically pipeline information (usually in the format of the page title followed by the URL) to Twitter via RSS feeds. Twitter Tools and Twitme for WordPress are popular WordPress plug-ins that integrate blog updates to Twitter. Assetize is an advertising syndicator mainly targeting at Twitter, and twitRobot is a bot tool that automatically follows other users and posts tweets. All these tools only require minimum human participation (like importing Twitter account information, or setting RSS feeds and update frequency), and thus indicate great automation.

Overall, humans tend to tweet manually and bots are more likely to use auto piloted tools. Cyborgs employ the typical human and bot tools. The cyborg group includes many human users who access their Twitter accounts from time to time. For most of the time when they are absent, they leave their accounts to auto piloted tools for management.

Q5. Do bots include more external URLs than humans? In our measurement, we find out that, most bots tend to include URLs in tweets to redirect visitors to external web pages. For example, spam bots are created to spread unsolicited commercial information. Their topics are similar to those in email spam, including online marketing and affiliate programs, working at home, selling fake luxury brands or pharmaceutical products\(^6\). However, the tweet size is up to 140 characters, which is rather limited for spammers to express enough text information to allure users. Basically, a spam tweet contains an appealing title followed by an external URL. Figure 7 shows the external URL ratios (namely, the number of external URLs included in tweets over the number of tweets posted by an account) for the three categories. The URL ratio of bot is highest. Some tweets by bot even have more than one URL\(^7\). The URL ratio of cyborg is very close to the bot level. A large number of cyborgs integrate RSS feeds and blog updates, which take the style of webpage titles followed by page links. The URL ratio of human is much lower, on average it is only 29%. When a human tweets what is he doing or what is happening around him, he mainly uses text and does not link pages often.

Q6. Are users aware of privacy and identity protection on Twitter? Twitter provides a protected option to protect user privacy. If it is set as true, the user’s homepage is only visible to his friends. However, the option is set as false by default. In our dataset of over 500,000 users, only 4.9% of them are protected users. Twitter also verifies some accounts to authenticate users’ real identities. Many such accounts belong to a type of bots that always append a spam link to tweets it re-tweets.
4. CLASSIFICATION

This section describes our automated system for classification of Twitter users. The system classifies Twitter users into three categories: human, bot, and cyborg. The system is made up of several components: the entropy component, the machine learning component, the account properties component, and the decision maker. The high-level design of our Twitter user classification system is shown in Figure 8. The components of the classification system determine what features are present for each user. Based on the combination of these features, the decision maker decides whether the user is a human, bot, or cyborg. The entropy component uses corrected conditional entropy to detect periodic or regular timing, which is a sign of automation. The machine learning component uses a variant of Bayesian classification to detect text patterns of messages posted by a Twitter user. On one hand, if the entropy or conditional entropy is low for the inter-tweet delays, it indicates periodic or regular behavior, a sign of automation. More specifically, some of the messages are posted via automation, i.e., a mix of order and disorder [12, 22].

The entropy rate is defined as either the average entropy per random variable given a previous sequence of random variables:

\[
H(X_m | X_1, ..., X_{m-1}) = H(X_1, ..., X_m) - H(X_1, ..., X_{m-1}).
\]

The conditional entropy of a random variable given a previous sequence of random variables is:

\[
H(X_m | X_1, ..., X_{m-1}) = H(X_1, ..., X_m) - H(X_1, ..., X_{m-1}).
\]

Then, based on the conditional entropy, the entropy rate of a random process is defined as:

\[
\overline{H}(X) = \lim_{m \to \infty} H(X_m | X_1, ..., X_{m-1}).
\]

The corrected conditional entropy is computed as a modification of Equation 3. First, the joint probabilities, \(P(X_1 = x_1, ..., X_m = x_m)\) are replaced with empirically-derived probabilities. The data distribution is binned into \(Q\) bins, i.e., values are converted to bin numbers from 1 to \(Q\). The empirically-derived probabilities are then determined by the proportion of unique sequences in the data. The entropy estimate and conditional entropy estimate, based on empirically-derived probabilities, are denoted as \(\overline{E N}\) and \(\overline{C E}\) respectively. Second, a corrective term, \(perc(X_m) \cdot \overline{E N}(X_1)\), is added to adjust for the limited number of sequences for increasing values of \(m\) [28]. The corrected conditional entropy, denoted as \(\overline{C E}\), is computed as:

\[
\overline{C E}(X_m | X_1, ..., X_{m-1}) = \overline{C E}(X_m | X_1, ..., X_{m-1}) + perc(X_m) \cdot \overline{E N}(X_1),
\]

where \(perc(X_m)\) is the percentage of unique sequences of length \(m\) and \(\overline{E N}(X_1)\) is the entropy with \(m\) fixed at 1 or the first-order entropy. The estimate of the entropy rate is the minimum of the corrected conditional entropy over different values of \(m\). The minimum of the corrected conditional entropy is considered to be the best estimate of the entropy rate from the limited number of sequences.

4.2 Machine Learning Component

The machine learning component uses the content of tweets to detect spam. We have observed that most spam tweets are generated by bots and only very few of them are manually posted by humans. Thus, the presence of spam patterns usually indicates automation. Since tweets are text, determining if their content is spam

More and more celebrities and famous organizations have applied for verified accounts. For example, Bill Gates has his verified Twitter account at http://twitter.com/billgates. However, in our dataset, only 1.8% of users have verified accounts.

Figure 8: Classification System
can be reduced to a text classification problem. The text classification problem is formalized as \( f : T \times C \rightarrow \{0, 1\} \), where \( f \) is the classifier, \( T = \{t_1, t_2, ..., t_n\} \) are the texts to be classified, and \( C = \{c_1, c_2, ..., c_k\} \) are the classes [31]. A value of 1 for \( f(t_i, c_j) \) indicates that text \( t_i \) belongs to class \( c_j \), whereas a value of 0 indicates it does not belong to that class. Bayesian classifiers are very effective in text classification, especially for email spam detection, so we decide to employ Bayesian classification for our machine learning text classification component.

In Bayesian classification, deciding if a message belongs to a class, e.g., spam, is accomplished by computing the probability that the document is from that class based on its content, e.g., \( P(C = \text{spam}|M) \), where \( M \) is a message and \( C \) is a class. If the probability is over a certain threshold, then the document is from that class.

The probability that a message \( M \) is spam, \( P(\text{spam}|M) \), is computed from Bayes theorem:

\[
P(\text{spam}|M) = \frac{P(M|\text{spam})P(\text{spam})}{P(M)}
\]

The message \( M \) is represented as a feature vector \((f_1, f_2, ..., f_n)\), where each feature \( f \) is one or more words in the message and each feature is assumed to be conditionally independent.

\[
P(\text{spam}|M) = \frac{P(\text{spam}) \prod_{i=1}^{n} P(f_i|\text{spam})}{P(\text{not spam}) \prod_{i=1}^{n} P(f_i|\text{not spam})}
\]

The calculation of \( P(\text{spam}|M) \) varies in different implementations of Bayesian classification. The implementation used for our machine learning component is CRM114 [4]. CRM114 is a powerful text classification system that offers a variety of different classifiers. The default classifier for CRM114 is Orthogonal Sparse Bigram (OSB), a variant of Bayesian classification, which has been shown to perform well for email spam filtering. OSB differs from other Bayesian classifiers in that it treats pairs of words as features.

### 4.3 Account Properties Component

Besides inter-tweet delay and tweet content, there are some Twitter account-related properties useful for the user classification. As shown in Section 3.3, obvious difference exists between the human and bot categories. The first property is the URL ratio. The ratio indicates how often a user includes external URLs in its posted tweets. External URLs appear very often in tweets posted by a bot. Our measure shows, on average the ratio of bot is 97%, while that of human is much lower at 29%. Thus, a high ratio (e.g., close to one) suggests bot and a low ratio implies human.

The second property is tweeting device makeup. According to Table 1, about 70% of tweets of human are posted by web and mobile devices (referred as manual devices), whereas about 87% of tweets of bot are posted by API and other auto-piloted programs (referred as auto devices). The third property is the followers to friends ratio. Figure 3 clearly shows the difference between human and bot. The fourth property is link safety, i.e., to decide whether external links in tweets are malicious/phishing URLs or not. We use Google’s Safe Browsing (GSB) API project [16], which allows us to check URLs against Google’s constantly-updated blacklists of suspected phishing and malware pages. The component converts each URL\(^8\) into hash values based on Google’s rules, and performs the local lookup from downloaded Google’s blacklists. Appearance in Google’s blacklists raises the red flag for security breach. GSB is also applied by Twitter for the link safety inspection [38].

\(^8\)For a shortened URL, the component uses PHP cURL to get the original one from the redirected HTTP response header instead of actually visiting the page.

The fifth property is whether a Twitter account is verified. No bot in our ground truth dataset is verified. The account verification suggests human.

The last property is the accuracy of the account registration date. According to Figure 5, 94.8% of bots were registered in 2009.

The account properties component extract these properties from the user log, and sends them to the decision maker. It assists the entropy component and the machine-learning component to improve the classification accuracy.

### 4.4 Decision Maker

Given an unknown user, the decision maker uses features identified by the above three components to determine whether it is a human, bot, or cyborg. It is built on Linear Discriminant Analysis (LDA) [26]. LDA is a statistical method to determine a linear combination of features that discriminate among multiple classes of samples. More specifically, its underlying idea is to determine whether classes differ in light of the means of a feature (or features), and then to use that feature (or features) to identify class. It is very similar to analysis of variance (ANOVA) [29] and (logistic) regression analysis [19]. However, a big difference is that LDA has a fundamental assumption that independent variables are normally distributed. In other words, it is assumed that variables represent a sample from a multivariate normal distribution. Our classification involves three classes, human, bot, and cyborg. Thus, it is a case of multiclass LDA. Multiclass LDA has the following key steps. First, it needs a training set and a test set that contain those samples already classified as one of the \( C \) classes. Samples in the two sets should not overlap with each other. Second, a discriminant model is created to use effective features to identify classes. Choosing features and assigning weights to features are the two important tasks in the model creation. In the early data collection stage, one usually includes several features to see which one(s) contributes to the discrimination. Some features are of very limited value for discrimination, and should be removed from the model. Our model uses forward stepwise analysis. In this way, the model is built step-by-step. At each step, all the features are evaluated, and the one that contributes most to the discrimination is added into the model. The selection process continues to next step. Suppose \( m \) features, \( v_1, v_2, ..., v_m \) are selected. Each class \( C_i \) has a classification function. With those functions, we can compute the classification score of an unknown sample for each class, by using the following linear equation:

\[
S_i = w_i0 + \sum_{i=1}^{n} w_i1 v_1 + w_i2 v_2 + ... + w_im v_m
\]

where \( j \) denotes the respective class, \( S_i \) denotes the classification score of the sample for class \( C_i \), and \( w_i0, w_i1, ..., w_im \) are the weights of \( j \)-th feature in class \( C_i \).

The sample is identified to belong to the class with the highest classification score. The model uses the training set to decide feature weights. Every sample in the training set is already known for the actual class it belongs to. The model keeps adjusting weights till it reaches the maximum accuracy for the training set. Third, the test set is used to validate the classification accuracy of the model. Since discriminant functions are derived from the training set, it is inappropriate to reuse it for the validation. It is easier for post hoc identification because it identifies what we already know has happened. The test set contains new data different from the training set, and generates more accurate validation results.

### 5. EVALUATION

In this section, we first evaluate the accuracy of our classification system based on the ground truth set (both the training and test datasets). Then, we apply the system to classify the entire dataset of over 500,000 users collected, and use the classification results to speculate the current composition of Twitter user population. Finally, we discuss the robustness of the proposed classification system against possible evasions.

#### 5.1 Methodology
As shown in Figure 8, the components of the classification system collaborate in the following way. The entropy component calculates the entropy (corrected conditional entropy) of inter-tweet delays of a Twitter user. The component only processes users with more than 100 tweets\(^5\). This limit helps reduce noise in detecting automation. A lower entropy indicates periodic or regular timing of tweeting behavior, a sign of automation, whereas a higher entropy implies irregular behavior, a sign of human participation.

The machine learning component determines if the tweet content is either spam or not, based on the text pattern it has learned. The content feature value is set to −1 for spam but 1 for non-spam. The account properties component checks all the properties mentioned in Section 4.3, and generates a real-number-type value for each property. Given a Twitter user, the above three components generate a set of features and input them into the decision maker. For each class, namely human, bot and cyborg, the decision maker calculates a classification score for the user, and identifies him as the class with the highest score. The training of the classification system and its accuracy are detailed in the following sections.

### 5.2 Classification System Training

The classification system needs to be trained before being used. In particular, the machine learning component and the decision maker require training. The machine learning component is trained on spam and non-spam datasets. The spam dataset consists of spam tweets and spam external URLs, which are detected during the creation of the ground truth data. Some advanced spam bots intentionally inject non-spam tweets (usually in the format of pure text without external URLs, such as adages\(^6\)) to confuse human users. Thus, we do not include such vague tweets without external URLs. The non-spam dataset consists of all human tweets and cyborg tweets without external URLs. Most human tweets do not carry spam. Cyborg tweets with links are hard to determine without checking linked web pages. They can be either spam or non-spam. Thus, we do not include this type of tweets in either dataset. Training the component with up-to-date spam text patterns on Twitter helps improve the accuracy.

The decision maker is trained to determine the weights of the different features for classification. We use Statistica, a statistical tool [33], to calculate the feature weights. More specifically, the datasheet of feature values and the actual class of users in the training set are inputted into the classifier. LDA generates a weight table (Table 2) to achieve the maximum accuracy. In other words, it includes as many users as possible whose classified class matches actual class. The weights are then used by the decision maker to classify users.

The larger the (standardized) weight, the larger is the unique contribution of the respective feature to the discrimination. Table 2 shows that, entropy, URL ratio, and manual/auto device percent-

### 5.3 Classification System Accuracy

To validate the accuracy of our proposed classification system, we create a test set containing one thousand users of each class. It shares no samples with the training set. The confusion matrix listed in Table 3 shows the classification results on the test set.

The “Actual” rows in Table 3 denote the actual classes of the users, and the “Classified” columns denote the classes of the users as decided by the classification system. For example, 949 in the “Human” row and column means that 949 humans were classified (correctly) as humans, whereas 51 in the “Human” row and “Cyborg” column means that 51 humans were classified (incorrectly) as cyborgs. There is no misclassification between human and bot.

We examine logs of those users being classified by mistake, and analyze each category as follows.

- For the human category, 5.1% of human users are classified as cyborg by mistake. One reason we find out is that, the overall scores of some users are lowered by spam content penalty. The tweet size is up to be 140 characters. Some patterns and phrases are used by both human and bot, such as “I post my online marketing experience at my blog at http://bit.ly/xT6kIM”. Please ReTweet it.” Another reason is that, the tweeting interval distribution of some human users is slightly lower than the entropy means, and they are penalized for that.
- For the bot category, 6.3% of bots are wrongly categorized as cyborg. The main reason is that, most of them escape the spam penalty from the machine learning component. Some spam tweets use very obscure text content, like “you should check it out since it’s really awesome. http://bit.ly/xT6kIM”. Without checking the spam link, the component cannot determine if the tweet is spam merely based on the text.
- For the cyborg category, 9.8% is mis-categorized as human, and 7.4% is mis-categorized as bot. The definition of cyborg as human-assisted bot or bot-assisted human, is ambiguous. A strict policy can categorize cyborg as bot, while a loose one may categorize it as human.

Overall, our classification system can accurately differentiate between human and bot. However, it is much more challenging for a classification system to distinguish cyborg from human or bot.

### 5.4 Twitter Composition

As the last part of this section, we use the classification system to automatically classify our whole dataset of over 500,000 users. We can speculate the current composition of Twitter user population based on the classification results. The system classifies the users as:

- 48.7% as human, 37.5% as cyborg and 13.8% as bot.

We speculate the population proportion of human, cyborg and bot category roughly as 5:3:1 on Twitter.
5.5 Resistance to Evasion

Now we discuss the resistance of the classification system to evasion attempts made by bots. Bots may deceive certain features, such as the followers to friends ratio as mentioned before. However, our system has two critical features that are very hard for bots to evade. The first feature is tweeting device makeup, which corresponds to the manual/auto device percentage in Table 2. Manual device refers to web and mobile devices, while auto device refers to API and other auto-piloted programs (see Section 4.3). Tweeting via web requires a user to login and manually post via the Twitter website in a browser. Posting via HTTP form is considered by Twitter as API. Furthermore, currently it is impractical or expensive to run a bot on a mobile device to frequently tweet. As long as Twitter can correctly identify different tweeting platforms, device makeup is an effective metric for bot detection. The second feature is URL ratio. Considering the limited tweet length that is up to 140 characters, most bots have to include a URL to redirect users to external sites. Thus, a high URL ratio is another effective metric for bot detection. Other features like timing entropy, bot could mimic human behaviors but at the cost of much reduced tweeting frequency. We will continue to explore new features emerging with the Twitter development for more effective bot detection in the future.

6. CONCLUSION

In this paper, we explore the problem of automation by bots and cyborgs on Twitter. As a popular web application, Twitter has become a unique platform for information sharing with a large user base. However, its popularity and very open nature have made Twitter a very tempting target for exploitation by automated programs, i.e., bots. The problem of bots on Twitter is further complicated by the key role that automation plays in everyday Twitter usage.

To better understand the role of automation on Twitter, we measure and characterize humans, bots, and cyborgs on Twitter. By crawling Twitter, we collected one-month of data with over 500,000 Twitter users with more than 40 million tweets. Based on the data, we identified features that can differentiate humans, bots, and cyborgs on Twitter. Using entropy measures, we determined that humans have complex timing behavior, i.e., high entropy, whereas bots and cyborgs are often given away by their regular or periodic timing, i.e., low entropy. In examining the text of tweets, we observed that a high proportion of bot tweets contain spam content. Lastly, we discovered that certain account properties, like external links, are also helpful in detecting automation.

Based on our measurements and characterization, we designed an automated classification system that consists of four main parts: entropy component, machine learning component, account properties component, and decision maker. The entropy component checks for periodic or regular tweet timing patterns; the machine learning component checks for spam content; and the account properties component checks for abnormal values of Twitter-account-related properties. The decision maker summarizes the identified features and decides whether the user is a human, bot, or cyborg. The efficacy of the classification system is evaluated through the test dataset. Moreover, we apply the system to classify the entire dataset of over 500,000 users collected, and speculate the current composition of Twitter user population based on the classification results.
